A characterization of first-order topological properties of planar spatial data

Michael Benedikt Christof Löding Jan Van den Bussche Thomas Wilke

Abstract

Planar spatial datasets can be modeled by closed semi-algebraic sets in the plane. We establish a characterization of the topological properties of such datasets expressible in the relational calculus with real polynomial constraints. The characterization is in the form of a query language that can only talk about points in the set and the "cones" around these points.

1 Introduction

A simple yet powerful way of modeling spatial data is using *semi-algebraic sets*. A (possibly infinite) subset of n-dimensional Euclidean space $\mathbf{R}^n$ is called semi-algebraic if it can be defined by a boolean combination of polynomial inequalities. The present paper is particularly concerned with sets in the plane, $\mathbf{R}^2$. First-order logic over the reals with arithmetic, order, and an extra binary predicate S, denoted here by FO[$\mathbf{R}$], then becomes a spatial query language, fitting in the well-known framework of constraint query languages introduced by Kanellakis, Kuper, and Revesz [10, 12]. For example, 'is the set S bounded?' can be expressed in FO[$\mathbf{R}$] as $\exists b \forall x \forall y (S(x,y) \rightarrow (-b < x < b \wedge -b < y < b))$. We will consider only sets that are closed in the ordinary topology on $\mathbf{R}^2$. This assumption is of great help from a technical point of view, and is harmless from a practical point of view.

A property of spatial datasets is called *topological* if it is invariant under topological transformations of the plane. More precisely, whenever the property holds for some A, it must also hold for any other A' that is the image of A under a homeomorphism of the plane (a bijection $f\colon \mathbf{R}^2 \rightarrow \mathbf{R}^2$ such that both f and f^{-1} are continuous). For example, the above-mentioned property 'the set is bounded' is topological, as is 'the set is a plane curve', and 'the set has three connected components'. In contrast, properties like 'the set contains a straight line segment' and 'the set is a perfect circle' are not topological. Apart from our interest in topological properties as a natural and mathematically well-motivated class of properties, they are also practically motivated by geographical information systems [5, 6, 7, 13].

Given the above setup, a natural question is to understand exactly which topological properties are first-order, i.e., expressible in FO[$\mathbf{R}$]. For example, 'the set is a plane curve' is first-order [18], but properties involving topological connectivity are not [2, 9, 12]. It is undecidable whether a given FO[$\mathbf{R}$]-sentence is topological [18]. Yet, this leaves open the possibility to syntactically capture topological FO[$\mathbf{R}$]—indeed a syntactic characterization has been a target of earlier work on the topic [17, 11]. This is what we will do in the present paper.

Our starting point is the work by Kuijpers, Paredaens and Van den Bussche [17], which considers the more basic question of understanding topological elementary equivalence: when are two sets indistinguishable by means of topological FO[$\mathbf{R}$]-sentences? A characterization was discovered in terms of the *cone types* occurring in the two sets. Indeed, semi-algebraic sets are topologically well-behaved in that lo-

cally around each point they are "conical" [3]. The cone of a point consists of the lines and regions arriving in the point, and can thus be represented as a (circular) string of L's (lines) and R's (regions). The characterization states that two sets are topologically elementary equivalent if and only if they have the same number of occurrences of every cone.

This characterization immediately suggests "Cone Logic" [11]: a topological query language that allows to express boolean combinations of properties of the form 'there are at most k occurrences of cones satisfying property γ'. Here, γ is any first-order property of cones viewed as circular strings. The first-order properties of strings are well-known to be the star-free regular languages [20]. It is tempting to conjecture that Cone Logic exactly captures topological FO[$\mathbf{R}$], but a proof has remained elusive; until now we only knew it for the special case of sets consisting of regions only, i.e., without L's in cones [11].

The main result of the present paper is that Cone Logic indeed captures topological FO[$\mathbf{R}$], over arbitrary closed semi-algebraic sets in the plane. Our proof develops extensively the idea of coding planar sets by finite structures [11]. This coding may well have other applications. Our proof also introduces new invariance arguments. These arguments show that first-order properties of structures enhanced with some form of "decoration", but invariant under the particular choice of decoration, are in fact expressible without referring to the decoration at all. Compare this to the famous example by Gurevich [1, Exercise 17.27], [4, Proposition 2.5.6], where the decoration is a total order. In that example the decoration is shown to be indispensable. In contrast, we will encounter kinds of decorations that are indeed dispensable. Finally, our proof not surprisingly relies on the collapse theorems for constraint queries on finite structures [15, 2]; as a matter of fact, the characterization we prove can be viewed as a lifting of collapse from finite structures to infinite sets.

Our proof also yields some variations and generalizations of the main result. For example, if one is interested in semi-linear sets only (i.e., sets definable using linear polynomials only), then Cone Logic still captures the first-order topological properties. Also, the result generalizes to o-minimal expansions of the reals [21].

In closing we should also mention previous work on topological properties not of single sets, but of entire collections of sets [16, 19]. This also covers the case of sets not necessarily closed, because such a general set can be represented by two closed ones, namely, its closure, and the closure of its complement. Even in the case of just two sets, Grohe and Segoufin [8] showed that topological elementary equivalence can no longer be characterized by looking at cones only. Yet, they were able to provide a characterization in the special case of collections of sets with "regular" points only. It would be interesting to lift this characterization to the level of queries, just like we have done here for the case of single sets.

2 Preliminaries

Spatial data In this paper, a *spatial dataset* (or just dataset) is defined as a semi-algebraic set in $\mathbf{R}^2$ that is closed in the ordinary topological sense. More concretely, this is a set that can be defined as a union of sets of the form $\{(x, y) \in \mathbf{R}^2 \mid P_1(x, y) \geqslant 0 \wedge \cdots \wedge P_m(x, y) \geqslant 0\}$, where each P_i is a polynomial in the variables x and y with integer coefficients. When all P_i's are linear, the set is called *semi-linear*.

First-order logic over the vocabulary $(0, 1, +, \times, <, S)$, with S a binary relation symbol, is denoted by FO[$\mathbf{R}$]. An FO[$\mathbf{R}$]-formula φ can be evaluated on a dataset A by letting variables range over $\mathbf{R}$, interpreting the arithmetic symbols in the obvious way, and interpreting $S(x, y)$ to mean that the point (x, y) is in A.

To formalize what it means for two datasets A and B to be topologically the same, we use the notion of *isotopy*. The intuition behind an isotopy is a continuous deformation of the plane. A and B are called *isotopic* if there is an isotopy

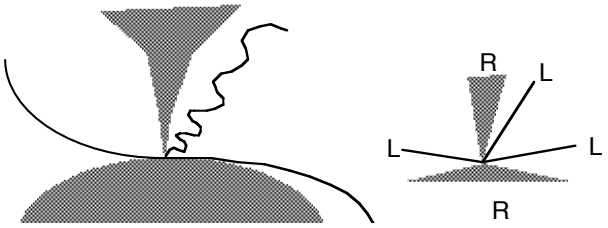

Figure 1: A dataset and the cone of one of its points.

h such that $h(A) = B$.[1] An FO[$\mathbf{R}$]-sentence φ is now called *topological* if whenever datasets A and B are isotopic, then $\varphi(A)$ is true if and only if $\varphi(B)$ is true.

Cones A known topological property of semi-algebraic sets [3] is that locally around each point they are conical. This is illustrated in Figure 1. Formally, for a point p and a real $\varepsilon > 0$, denote the closed disk with center p and radius ε by $D(p, \varepsilon)$, and denote its bordering circle by $C(p, \varepsilon)$. Then for every point p of a dataset A there exists an $\varepsilon > 0$ such that $D(p, \varepsilon) \cap A$ is isotopic to the planar cone with top p and base $C(p, \varepsilon) \cap A$. We thus refer to *the cone of p in A*.

Every dataset A is also conical around infinity. Formally, there exists an $\varepsilon > 0$ such that $\{(x, y) \mid x^2 + y^2 \geqslant \varepsilon^2\} \cap A$ is isotopic to $\{\lambda \cdot (x, y) \mid (x, y) \in C((0, 0), \varepsilon) \cap A \wedge \lambda \geqslant 1\}$. We can indeed view the latter set as the cone with top ∞ and base $C((0, 0), \varepsilon) \cap A$, and call it *the cone at ∞ in A*.

We will identify cones with circular lists. The cone having a full circle as its base (which appears around interior points) is represented by the single letter F. Any other cone can be represented by a circular list of L's and R's (for "line" and "region") which describes the cone in a complete clockwise turn around the top. For example, the cone of Figure 1 is represented by $(LLRLR)$. The cone with empty base (which appears around isolated points) is represented by the empty list ( ).

There are only three cones that can occur infinitely often in a dataset: F, (LL) (the cone around points on curves), and (R) (the cone around points on the smooth border of a region). We call these the *regular cones*; all other cones are called *singular*. The points with a singular cone must be finite in number in any dataset. These points are called the *singular* points of the dataset.

3 The characterization

We will establish a characterization of the properties of datasets expressible by topological FO[$\mathbf{R}$]-sentences. Our characterization will be in terms of conditions on the cones occurring in the datasets, as well as on the number of such cones.

Given that cones are circular strings over the alphabet $\{L, R\}$ (except for the special cone F), it is convenient to use standard formal language theory to define properties of cones. Specifically, recall that a *star-free regular expression* over a finite alphabet Σ is an expression built up from the atoms Σ^*, ϵ, and a, for $a \in \Sigma$, using the operations union, difference, and concatenation. Such expressions define string languages, i.e., sets of strings over Σ, in the obvious way. If a string s is in the language defined by e, we also say that s *satisfies* e.

But these expressions can also be used to define sets of circular strings. It suffices to agree that a circular string satisfies expression e if it

[1] Formally, an isotopy is a homeomorphism of the plane that is isotopic to the identity. Two homeomorphisms f and g are isotopic if there is a function $F : \mathbf{R}^2 \times [0, 1] \to \mathbf{R}^2$ such that

1. for each $t \in [0, 1]$, the function $F_t : \mathbf{R}^2 \to \mathbf{R}^2 : p \mapsto F(p, t)$ is a homeomorphism;
2. F_0 is f and F_1 is g; and
3. $F(p, t)$ is continuous in t.

A more relaxed notion of "being topologically the same" is to simply require that B is the image of A under a homeomorphism rather than an isotopy. The only difference between the two notions is that the latter considers mirror images to be the same, while the former does not. Indeed, every homeomorphism either is an isotopy itself, or is isotopic to a reflection [14]. All the results we will present under isotopies have close analogues under homeomorphisms.

equals the circularization of a normal string satisfying e. For example, the expression LR^*L defines all cones that have only two L's, and these L's must be consecutive.[2]

This leads us to a natural topological query language called "Cone Logic" or $\mathcal{CL}$ for short. A $\mathcal{CL}$-sentence is a boolean combination of atomic conditions of the following possible forms:

1. F, meaning that there exists a point in the dataset with cone F (in which case there will automatically be infinitely many such points).

2. $F(\infty)$, meaning that the cone at infinity is F.

3. $|e| \geqslant n$, with e a star-free regular expression over $\{L, R\}$ and n a natural number, meaning that there are at least n points in the dataset whose cone satisfies e.

4. $e(\infty)$, meaning that the cone at infinity satisfies e.

Note that properties of datasets expressed in $\mathcal{CL}$ are always topological. Every $\mathcal{CL}$-sentence can be equivalently expressed in FO[**R**], i.e., for each $\mathcal{CL}$-sentence ψ there exists an FO[**R**]-sentence φ such that $\psi(A) = \varphi(A)$ for each dataset A. Our main result is that $\mathcal{CL}$ actually characterizes the topological FO[**R**]-sentences:

Theorem. *For each topological* FO[**R**]*-sentence φ there exists a $\mathcal{CL}$-sentence ψ such that $\varphi(A) = \psi(A)$ for each dataset A.*

4 Flower normal form

For simplicity of presentation, in proving our characterization we will restrict attention to bounded datasets, so that the point at infinity can be ignored. Incorporating infinity makes the proof technically more complicated, but it involves no new insights.

[2]The subexpression R^* can be viewed as a shorthand for $\Sigma^* - \Sigma^* L \Sigma^*$ with $\Sigma = \{L, R\}$.

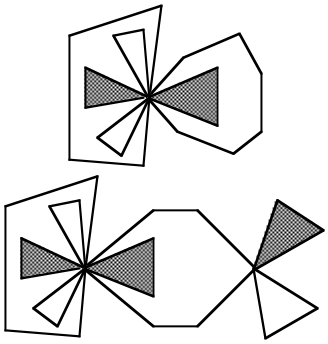

Figure 2: A single flower and a flower pair.

A more drastic restriction is to datasets in what we call *flower normal form*. Such a dataset, called a *flower dataset* for short, consists of a number of connected components, of two possible kinds: *single flowers* and *flower pairs*. Both are illustrated in Figure 2.

- A single flower is a connected dataset with exactly one singular point, where every R in the cone is a small "lobe" emanating from the point but meeting no other R's. Necessarily, every line emanating from the point also arrives somewhere else in the point, i.e., all lines are *self-lines*. Note that a self-line is visible as two L's in the cone of the singular point, so a single flower has an even number of L's in the cone.

- A flower pair consists of two single flowers, except that some of the lines cross between the two singular points. These *cross-lines* must be consecutive: between two emanating cross-lines there cannot be a self-line. Note that a cross-line is visible as one L in the cone of each of the two singular points. Paired flowers need not have an even number of L's in their cone.

The justification for flower normal form comes from the notion of *topologically elementary equivalence*, or t.e.e. Two datasets are t.e.e. if no topological FO[**R**]-sentence distinguishes between them. We recall:

Theorem 1 ([17]). *Two datasets are t.e.e. if and only if they have the same cone at ∞, and every other cone occurs exactly the same number of times in both sets (a finite number for singular cones, or infinitely often for regular cones).*

By this theorem, every bounded dataset is t.e.e. to a flower dataset, provided the set does not have any connected components consisting of regular points only. A simple argument (omitted) shows, however, that if our characterization holds over the datasets without such regular components, then it holds over all datasets. So from now on we can focus on flower datasets.

5 Overview of the proof

The global outline of our proof is that for any topological FO[**R**]-sentence φ we can find two natural numbers k and ℓ such that any two flower datasets that are "(k, ℓ) equivalent" are indistinguishable by φ. Hence, φ is a union of (k, ℓ)-equivalence classes. Now (k, ℓ)-equivalence will have two good properties: it will be of finite index, and every equivalence class can be defined in $\mathcal{CL}$. As a consequence, φ can be written as a finite disjunction of $\mathcal{CL}$-sentences, and we will have proven our characterization.

To define (k, ℓ)-equivalence, we need the notion of a *cone structure*. Up to isomorphism, this is a finite structure with domain $\{1, \ldots, n\}$, for some natural number n. Every element is labeled with L or R. Moreover, the structure includes a ternary relation B (for "between"). $B(x, y, z)$ holds if y comes before z in the following sequence: x, $x+1$, …, n, 1, 2, …, $x-1$. We say that y is between x and z. So, a cone structure is an explicit representation of a cone. Note that a cone structure is the circular version of what is known as a *word structure* over the alphabet $\{L, R\}$; in word structures we have the total order on $\{1, \ldots, n\}$ instead of the betweenness relation.

Cone structures allow us to use first-order logic sentences over the vocabulary (L, R, B) to express properties of cones. In particular, a *k-type* is a maximally consistent conjunction of first-order sentences of quantifier rank k, over the vocabulary (L, R, B) of cone structures. Now two datasets are called *(k, ℓ)-equivalent* if for every k-type τ, they either have precisely the same number of singular cones of type τ, or the two numbers are both at least 3ℓ. That (k, ℓ)-equivalence classes are indeed definable in $\mathcal{CL}$ follows easily from the well-known translation of first-order sentences over word structures to star-free regular expressions [20].

The proof that two (k, ℓ)-equivalent flower datasets are indistinguishable by φ proceeds by transforming one dataset into the other, using a repertoire of transformations that are indistinguishable by φ. They are the following:

Marrying and divorcing: Two single flowers can be married to become a flower pair with the same cones (with, e.g., all lines going across). The inverse of this transformation is allowed as well.

Spouse swapping: Two flower pairs $\{f_1, f_2\}$ and $\{f_3, f_4\}$ can be replaced by two other flower pairs $\{g_1, g_3\}$ and $\{g_2, g_4\}$, such that the cones of f_i and g_i are identical for $i = 1, 2, 3, 4$.

Substitution: A single flower can be replaced by any other single flower whose cone has the same k-type. A flower pair can be replaced by any other flower pair, as long as the pair of cone k-types is the same.

Stretching: For any k-type with at least ℓ occurrences of single flowers of that cone type, we can add any number of additional single flowers of the type. For any pair of k-types with at least ℓ occurrences of a flower pair with that pair of cone types, we can add any number of additional such flower pairs.

Formally, we will prove:

Lemma 1. *For any topological* FO[**R**]*-sentence φ there exist k and ℓ such that the above transformations are indistinguishable by φ.*

Lemma 2. *Any two (k, ℓ)-equivalent flower datasets can be transformed into each other by the above transformations.*

Lemma 2 is shown by marrying the cone types in a canonical way, after first stretching their numbers to match; the details are in the Appendix. Proving Lemma 1 is a large enterprise which is taken up in the next two sections. Note that the legitimacy of Marrying, Divorcing, and Spouse Swapping, which do not mention k and ℓ anyway, already follows from Theorem 1.

6 Codes and drawings

We are going to represent flower datasets by abstract finite structures, which we call *codes*. A code is a disjoint union of components, of two possible forms: *single cycles* and *cycle pairs*. A single cycle represents a single flower, and a cycle pair represents a flower pair.

Single cycles A single cycle is a word structure over the alphabet $\{L, R\}$, with two modifications. First, the number of L's must be even. Second, the structure includes a matching[3] G on the L-labeled nodes that is *planar* in the following sense: if $i < j < k < \ell$, then it is forbidden that $G(i, k)$ and $G(j, \ell)$ both hold.

Note that a cycle is not cyclic at all, but we still use the name because cycles will always have a circular interpretation: we will never need to distinguish two cycles that are the same up to rotation. In particular, there is an obvious notion of a single flower Y being a *drawing* of a single cycle C, which we do not define formally, but illustrate in Figure 3. When Y is a drawing of C, then Y is a drawing of every rotation of C as well.

Cycle pairs A cycle pair is a disjoint union of two single cycles, with two modifications. First, the number of L's in each cycle need not be even.

[3] A matching on a set X is the symmetric closure of a bijection from one half of X to the other half.

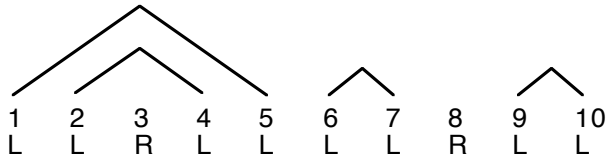

Figure 3: The single flower of Figure 2 is a drawing of the single cycle shown here.

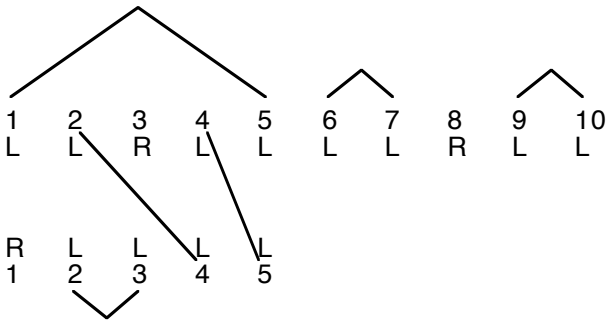

Figure 4: The flower pair of Figure 2 is a drawing of the cycle pair shown here.

Second, instead of G being a planar matching on the L's of each single cycle separately, a subsequence of consecutive L's in one cycle is now matched by G to a subsequence of consecutive L's in the other cycle. Here, we call two L's consecutive if there is no other L in between (there may be R's), where "between" has its meaning as in cone structures.

Clearly, the cross-matches by G model the cross-lines in a paired flower, and again there is an obvious notion of a flower pair being a drawing of a cycle pair, illustrated in Figure 4.

Codes A *code* is now defined as a disjoint union of single cycles and paired cycles. We denote the vocabulary of codes, consisting of $<$, L, R, and G by Γ.

A flower dataset A is called a *drawing* of a code C if A has a separate drawing for every single cycle and every cycle pair of C, and nothing more. In that case we also say that C is a *representation* of A.

The following proposition demonstrates the utility of codes.

Proposition 1. *For any topological* FO[**R**]*-sentence φ there exists a first-order sentence ψ over Γ such that for every flower dataset A, and every representation C of A, we have $\varphi(A) = \psi(C)$.*

Proof. An *embedded code* is a code embedded in **R**, so the abstract nodes happen to be real numbers. An embedded code is called *well embedded* if within each component, the ordering on the nodes as real numbers agrees with the order given by the cycles. Moreover, all nodes belonging to one component must be either all smaller or all larger (in the real order) than all nodes belonging to another component, and in a cycle pair all nodes of one of the cycle are all smaller than all nodes of the other cycle.

Until now, FO[**R**]-formulas were always understood to be over the vocabulary of **R** $(0, 1, +, \times, <)$ expanded with a binary relation S to address the spatial dataset to be queried. But in the following lemma we use FO[**R**]-formulas on embedded codes, where we expand **R** not with S but with Γ. We refer to such formulas as FO[**R**]-formulas over Γ.

Lemma 3. *There exists an* FO[**R**]*-formula $draw(x, y)$ over Γ such that for any well-embedded code C, the set $\{(x, y) \in \mathbf{R}^2 \mid (x, y) \in draw(C)\}$ is t.e.e. to a drawing of C. If C is not a well-embedded code, then $draw(C)$ is empty.*

We omit the proof, but Figure 5 gives an idea of the construction.

Consider now the composed query $\varphi \circ draw$. By the natural-active collapse theorem [2], we can equivalently express $\varphi \circ draw$ by an FO[**R**]-sentence χ over Γ in which the quantifiers range over the nodes of C only. Moreover, the query is *order-generic:* for any embedded Γ-structure C, and for any monotone bijection ρ of **R**, we have $\varphi(draw(C)) = \varphi(draw(\rho(C)))$. Hence, by the generic collapse theorem [15, 2], we can further reduce χ to a first-order sentence ψ just over Γ. In other words, ψ sees just the abstract code, not the actual embedding, were it not that it still sees a total order on *all* nodes, instead of just the partial orders given within the cycles.

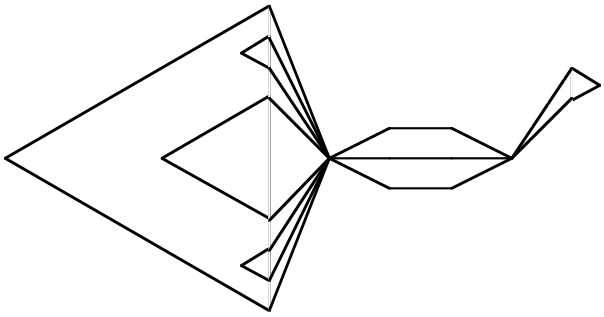

Figure 5: "Proof by picture" of Lemma 3. The figure shows a systematic drawing of an embedded cycle pair (involving only L's).

Fortunately, we can get rid of the order among cycles using a model-theoretic argument which we just sketch. Observe that ψ is actually invariant under the particular way the different cycles compare to each other. Hence, if r is the quantifier rank of ψ, we may fix an arbitrary order on r-types and assume that the order among the components is according to their r-types. This leaves us only with the order among components of the same r-type, and the order among the two cycles in a cycle pair. These can be dispensed with by an Ehrenfeucht-Fraïssé game argument. □

As we will see in the next section, Proposition 1 opens the door towards proving the remaining Lemma 1. But the proposition is also interesting in itself: it shows that topological FO[**R**]-queries can be supported by a standard finite relational database representation of the spatial dataset.

7 Invariance arguments

Fix a topological FO[**R**]-sentence φ, and let ψ be obtained from Proposition 1. Now observe that ψ must be invariant under rearrangement of the planar matching G in any of the components of a code C. Indeed, in a drawing A of C, this yields a rearrangement of self-lines (and possibly cross-links in a flower pair), and φ cannot notice such rearrangements by t.e.e. Hence, ψ cannot

notice them in C either. We say in short that ψ is *planar invariant*. Moreover, ψ is invariant under rotation of the cycles. We say that ψ is *rotation invariant*.

The following lemma, proven by a simple Ehrenfeucht-Fraïssé game argument (omitted), shows that we can "push down" invariance to the level of the separate connected components of a code.

Pushdown Lemma. *Every invariant sentence over codes can be rewritten as a boolean combination of conditions of the form $|\gamma| \geqslant n$, with γ again invariant. Such a condition means that that there at least n components in the code satisfy γ.*

We are now ready for the

Proof of Lemma 1. As already mentioned, we must deal only with the transformations of Substitution and Stretching.

Substitution revolves around eliminating the major difference between cycles and cones, namely that codes contain the matching relation G. The following crucial lemma allows us to get rid of G. The proof, which is quite involved, is given in the Appendix.

Invariance Lemma. *Every first-order sentence over word structures equipped with planar matchings G, that is planar-invariant, can be written without G, i.e., as a first-order sentence over words.*

We would like to apply the Invariance Lemma to each component sentence γ from the Pushdown Lemma that works on single cycles, so that it can be rewritten without G. Since γ is also rotation-invariant, it is then an easy matter to rewrite it further to get a cone sentence. If we then take k to be the maximal quantifier rank of all the resulting component cone sentences, we obtain the desired result that Substitution of a single flower is indistinguishable by φ. Moreover, if we take ℓ to be the maximal bound n from the Pushdown Lemma, we obtain the same for Stretching of a single flower.

There is a small problem, however, since the Invariance Lemma deals with word structures equipped with a total planar matching, while cycles have a planar matching only on their L's. We can solve this as follows. Let r be the quantifier rank of γ. A standard Ehrenfeucht-Fraïssé game argument shows that γ cannot distinguish two words that agree if we count blocks of R's only up to 2^r. This allows us to view γ as a sentence on the word consisting of the L's only, but where each L is labeled with one of the new letters P_i for $i = 0, \ldots, 2^r$, where P_i for $i < 2^r$ means that there are exactly i R's following the element, and P_{2^r} means that there are at least 2^r R's. After using this abstraction, we can then apply the Invariance Lemma. Other applications of the Invariance Lemma in the next paragraphs must also be interpreted in this manner.

For flower pairs the argument for Substitution is a bit more complicated. First, observe that by t.e.e. we can always rearrange G so that there is either exactly one cross-match, or none at all. The first case occurs when the number of L's in each cycle is odd; the second when the number is even. Hence, if we restrict a component sentence γ to pairs with even cross-matches, then we can rewrite it as an assertion about cone types; in this case we can arrange for there to be no cross-matches, leaving us with simply two word structures equipped with planar matchings, from which the matching can be removed using the Invariance Lemma. Similarly if we restrict to pairs with odd cross-matches; the cross-matched pair can be replaced in favor of a distinguished label for the ends of the crossing line, and the Invariance Lemma can be applied to these enhanced words. From this we see not only that Substitution is justified for pairs of the same parity, but also that γ can be written as a sentence using only the cone signature, provided that a parity check is permitted in addition to first order logic.

Now on the other hand, again by t.e.e. we can also maximize the number of cross-matches, so that the smaller of the two cycles has all its lines crossing to the larger cycle. Again incorporating

blocks of R's into the labels of the L's as before, this yields a view of the cycle pair as a word of pairs of letters, followed by a word comprising the unpaired elements from the larger cycle, on which we still have a planar matching G. Over this view, a component sentence γ can be broken up into sentences γ_1 quantifying over the letter pairs and sentences γ_2 quantifying over the unpaired elements. The planar matching G can be removed from the latter sentence using the Invariance Lemma. Viewing now the unpaired elements as paired with a dummy letter, we obtain a first-order sentence over words over a pair alphabet.

So on the one hand γ expresses a combination of regular conditions on the words in a pair (by the paragraph before the previous one), and on the other hand it expresses a star-free regular condition on the word pair (viewed as a word over the pair alphabet). A simple argument (omitted) then shows that γ must already be a combination of star-free regular conditions on the separate words. Since these conditions are rotation-invariant (here we apply a mini-version of the Pushdown Lemma), we have arrived at the desired combination of cone types, which justifies Substitution in general, as well as Stretching for pairs. □

8 Discussion

In Section 3 we already mentioned that $\mathcal{CL}$ can indeed be simulated in FO[**R**]. Actually, this is already possible in FO[<], the fragment of FO[**R**] that does not use arithmetic on **R**, only order. As an immediate corollary of our theorem we thus obtain:

Corollary 1. *Every topological* FO[**R**]*-sentence on closed semi-algebraic sets in the plane can already be expressed in* FO[<].

This is a nice analog of the generic collapse theorem [2] used in the proof of Proposition 1, which says exactly the same for order-generic FO[**R**]-sentences on finite structures over the reals. Thus our theorem can be viewed as a "lifting" of collapse from finite structures to infinite datasets.

We note that in the proof of Theorem 3, *semi-algebraic* sets play a very small role. The drawing arguments (as well as the drawings used in the proof of Theorem 1 [17]) all remain within semi-linear sets, and hence the entire argument could have taken place there. Hence we have also proved:

Corollary 2. *Every* FO[**R**]*-query that is topological over (closed) semi-linear datasets is equivalent over semi-linear datasets to a CL sentence.*

Note that there are FO[**R**]-queries that are topolical over semi-linear datasets but not over all semi-algebraic datasets. Indeed one can write an FO[**R**]-sentence (even without multiplication) that is true exactly for those datasets that are "line-like"—definable with addition (possibly with real parameters). Such a sentence is a tautology over semi-linear datasets but is not topological over semi-algebraic ones.

The theorem also lifts up to any family of sets that includes the semi-linear sets and in which every set is isotopic to a semi-linear one; for example, this is known to hold for the collection of sets definable in an *o*-minimal expansion of the real ordered group.

Likewise we use little about FO[**R**]*queries*. Our argument goes through for constraint query languages over expansions of the real field which have the properties that: a) definable sets are isotopic to semi-linear sets and b) the generic collapse theorem holds. Both of these are known to hold in every o-minimal expansion of the reals [21, 2]. Hence, for example, if we add exponentiation to our query language, we get:

Corollary 3. *Every* FO$[+, *, <, e^x, S]$ *query that is topological over closed semi-linear (resp. semi-algebraic,* FO$[+, *, <, e^x]$ *definable) sets in the plane is equivalent over semi-linear (resp. semi-algebraic,* FO$[+, *, <, e^x]$ *definable) sets to a CL sentence.*

Appendix

Proof of Lemma 2

Let C and D be (k, ℓ) equivalent datasets. We will assume that pairs in C and D have at most one cross-link; i.e. they are either single flowers or a flower pair with a single link. All of our rewriting will remain within this more restricted class. Clearly, moving into this class can be done using Substitution. We call a cone-type *abundant* in C if there are at least 3ℓ flowers in C with that type (married or single). We call a type *essentially bachelor* if all of its realizations have an even number of crosslinks, and *marriageable* otherwise.

First consider the types that are abundant in C and essentially bachelor. By (k, ℓ) equivalence, we know that these must be abundant in D as well, and hence by Stretching we can ensure that there are the same number of single flowers in C and D with that type.

We next arrange the marriageable abundant types. We need the following:

Claim. *Let C be a dataset and T be a type that is marriageable and abundant in C. We can transform C so that all of its realizations are married. i.e. we can rewrite C using (k, ℓ)-equivalences to get a dataset in which all of the realizations of T are married (while remaining within the normal form above) .*

Proof of Claim. Fix C and T, and suppose there are j single-flowers of type T in C and p married pairs containing a member of type T.

We can assume $j > 0$, since otherwise we are done. We first show that j can be made larger than ℓ. If it is not so large already, then p must be larger than 2ℓ (since T is abundant). But then we could marry off ℓ of the married T instances to each other. Once we did this, we could apply Stretching to make the number of (T, T) pairs as large as we like. We could then take some of these pairs and replace them by two single-flower instances, since we know there are both (T, T) pairs and single-flower pairs. Hence j can be made larger than ℓ.

Once j can be made larger than ℓ, we know it can be stretched to any number, so in particular j can be made large and even. Hence in particular, we could remarry all of these single-flower instances to themselves, and thus assume that j is in fact 0 – all of the instances are married. □

We now proceed to show that, given instances C and D and a type T that is abundant in C (hence in D) and which is marriageable, we can rewrite C and D so that the marriage graphs of C restricted to instances of T and their mates is isomorphic to the matching graph of realizations of T and their mates in D. So fix T; by the claim we can assume that all realizations are married. Let p be the number of married realizations of T in C.

Case 1: Suppose that there is some other type W such that there are $h > 3\ell$ married flowers of type W in C. First, we can ensure that h is much bigger than p; we can do this by marrying some of the W flowers to each other and then stretching the number of (W, W) pairs. We can then take p of these and marry them to the p married realizations of T, by Spouse Swapping. What we have shown is that we can arrange that all of the married instances of T are married to flowers of the same type. We do the same in D. Now we can stretch this type pair in one of the models to ensure that the number of (W, T) pairs is the same.

Case 2: Every other type W has at most 3ℓ married realizations. Then the number of these other non-T married realizations must be the same in C as in D. In particular, the parity of the married realizations of T is the same in both structures. If it is even we marry the other guys to each other and marry the elements of type T to each other (stretching the number of (W, W)

elements to match in both structures). If it is odd, then in each structure we marry one of the T's to one of these non-abundant types, and the rest to each other.

This completes the abundant types, and in fact, we now have a correspondence between realizations of the abundant types and their mates in both structures. The remaining non-abundant types that are not in this correspondence can be matched up the same way in each structure just by rearranging the marriage pattern, since by (k, ℓ) equivalence we know that the two structures must agree exactly on the number of realizations of these types.

Proof of the Invariance Lemma

We will actually present a proof of the version of the Invariance Lemma that is about circular words rather than linear words. This version is equivalent with the original.

We will use the following notation for various vocabularies. For words over Σ we use $\mathcal{L}_W\Sigma = (<, S, \Sigma)$, where S is the successor relation easily definable from $<$. For circular words over Σ we use $\mathcal{L}_C\Sigma = (B, S, \Sigma)$, where we have betweenness instead of order. Finally, for cycles (equipped with a planar matching) we use $\mathcal{L}_{CG}\Sigma = (B, S, G, \Sigma)$. For historical reasons we will refer to a cycle equipped with a planar matching as a "cycle bijection" or a "CB" for short. Wherever Σ does not matter we omit it from our notation.

With every FO$\mathcal{L}_{CG}$ formula ϕ, we associate the $\mathcal{L}_{CG}$ query $P(\phi)$ which consists of all planar cycle bijections satisfying ϕ. Similarly, when ϕ is an FO$\mathcal{L}_W$ formula, then $W(\phi)$ denotes the set of all $\mathcal{L}_W$ structures satisfying ϕ.

Then a restatement of the Invariance Lemma is:

For every planar-invariant FO$\mathcal{L}_{CG}\Sigma$ formula ϕ there exists an FO$\mathcal{L}_C\Sigma$ formula $\phi^\dagger$ such that $P(\phi) = P(\phi^\dagger)$.

By abuse of notation, we also write $W(Q)$ for the set of all $\mathcal{L}_W$ structures corresponding to planar CB's in Q, when Q is an $\mathcal{L}_{CG}$ query. Similarly, when ϕ is an FO$\mathcal{L}_{CG}$ formula, we write $W(\phi)$ for $W(P(\phi))$. For simplicity, we also identify words over an alphabet Σ and $\mathcal{L}_W\Sigma$ structures.

Using the above notation, we can state the following helpful lemma.

Lemma 4. *Let Q be a planar-invariant $\mathcal{L}_{CG}\Sigma$ query and ϕ an $\mathcal{L}_W\Sigma$ formula such that $W(Q) = W(\phi) \cap (\Sigma\Sigma)^*$. Then there exists an FO$\mathcal{L}_C\Sigma$ formula ϕ^* such that $P(\phi) = P(\phi^*)$.*

Proof. We only describe the construction of ϕ^*; the correctness of ϕ^* can be proved easily by induction.

The general idea is to replace the atomic subformulas of ϕ by appropriate $\mathcal{L}_C\Sigma$ formulas. The only problem here is $<$, because in a CB, we don't have an order relation, but only a cycle with "betweenness". The remedy is to "anchor" our formula.

We first choose a fresh variable x_m. Then, ϕ^* can simply be chosen as $\exists x_m \phi'$ where ϕ' is obtained from ϕ by substituting

- $x < y$ by $B(x, y, x_m) \vee (x = x_m \wedge x \neq y)$ and
- $S(x, y)$ by $S(x, y) \wedge y \neq x_m$.

□

This tells us that in order to prove the conjecture we only need to show that for every planar-invariant FO$\mathcal{L}_{CG}\Sigma$ query Q there exists an FO$\mathcal{L}_W\Sigma$ query L' such that $W(Q) = L' \cap (\Sigma\Sigma)^*$. In

other words, we have to find a "completion" of $W(Q)$ with appropriate words of odd length such that the resulting language is first-order definable.

We will, in fact, prove a stronger statement, namely that the above is true already when Q is invariant under a smaller class of CB's. We say that a cycle bijection is a chain cycle bijection if it satisfies

$$\forall xy(G(x,y) \to S(x,y)) \ ,$$

and a parenthetical cycle bijection if it satisfies

$$\forall x_0x_1x_2x_3(S(x_0,x_3) \wedge S(x_1,x_2) \to (G(x_0,x_2) \leftrightarrow G(x_3,x_1))) \ .$$

A chainpar cycle bijection satisfies one of the two conditions. What we will really show is that the above claim already holds for chainpar-invariant queries.

Languages and Counters

Let Σ be an alphabet and $L \subseteq \Sigma^*$ a language. We use $\leftrightarrow_L$ to denote the relation defined by $u \leftrightarrow_L v$ if $u \in L$ and $v \in L$, or $u \notin L$ and $v \notin L$. Nerode's congruence for L, denoted $\equiv_L$, is defined by $u \equiv_L v$ if $uw \leftrightarrow_L vw$ for every $w \in \Sigma^*$.

When L is regular, then A_L denotes the minimum DFA for L (whose states are the equivalence classes of $\equiv_L$).

Let $A = (S, \Sigma, s_{\text{in}}, \delta, F)$ be a DFA. A *counter* of A is a pair (s,u) with $s \in S$ and $u \in \Sigma^*$ such that $\delta(s,u) \neq s$ and $\delta(s,u^n) = s$ for some $n > 0$. The smallest such n is called the *period* of (s,u), and $|u|$ is called the *progression* of (s,u). An (n,m)-counter is a counter with period n and progression m. We extend this to sets of natural numbers and use, for instance, the expression $(2,\text{odd})$-counter to denote a $(2,m)$-counter for some odd m.

The concept of counters can directly be adapted to languages (rather than automata) by saying that a pair (u,v) with $u,v \in \Sigma^*$ is a counter of a language L if there exists $n > 0$ such that $u \not\equiv_L uv$ and $uv^n \equiv_L u$. For a regular language, this is equivalent to saying that $(\delta(s_{\text{in}},u),v)$ is a counter of A_L. The word u is called the *offset* of the counter.

Chain-Invariant Queries

When Q is an $\mathcal{L}_{CG}\Sigma$ query, we write $W_{\text{chain}}(Q)$ for the set of all $\mathcal{L}_W\Sigma$ structures corresponding to chain CB's in Q.

In this subsection the objective is to show that for every chain-invariant FO$\mathcal{L}_{CG}\Sigma$ query Q, the language $W_{\text{chain}}(Q)$ has only counters of a certain type:

Proposition 2. *For every chain-invariant FO$\mathcal{L}_{CG}\Sigma$ query Q, $W_{\text{chain}}(Q)$ is regular and has only $(2,\text{odd})$-counters.*

For every alphabet Σ, let $\bar{\Sigma}$ be a disjoint copy of Σ and Σ_{alt} the union of these two sets. A word is called alternating when it belongs to $(\Sigma\bar{\Sigma})^*$ and a language is called *alternating* when it consists of alternating words only. When Q is an $\mathcal{L}_{CG}\Sigma$ query, we write $W_{\text{alt}}(Q)$ for the set of all alternating $\mathcal{L}_W\Sigma_{\text{alt}}$ structures corresponding to chain CB's in Q in the following sense. A position x in the word will be labeled with an element from Σ iff in the CB this position satisfies $\exists y G(x,y)$.

The homomorphism $\pi\colon {\Sigma_{\text{alt}}}^* \to \Sigma^*$ defined by $\pi(a) = \pi(\bar{a}) = a$ for $a \in \Sigma$ is called the *natural projection.*

Remark 1. *For every chain-invariant $\mathcal{L}_{CG}\Sigma$ query Q,*

$$W_{\text{chain}}(Q) = \pi(W_{\text{alt}}(Q)) \ .$$

We now prove a first lemma.

Lemma 5. *For every $FO\mathcal{L}_{CG}\Sigma$ formula ϕ there exists an $FO\mathcal{L}_W\Sigma_{\text{alt}}$ formula ϕ_{alt} such that*

$$W_{\text{alt}}(Q) = W(\phi_{\text{alt}}) \ .$$

Proof We only describe the formula ϕ_{alt}; its correctness can be proved by a simple induction.

For every $\mathcal{L}_{CG}$ formula ϕ, let ϕ_{alt} be defined by $\bar{\phi} \wedge \alpha$ where α is the conjunction of

$$\forall x \forall y (Sxy \rightarrow (\Sigma x \leftrightarrow \bar{\Sigma} x)) \wedge \forall x (\text{Min}(x) \rightarrow \Sigma x) \wedge \forall x (\text{Max}(x) \rightarrow \bar{\Sigma} x)$$

with $\text{Min}(x)$ and $\text{Max}(x)$ defined by

$$\begin{aligned} \text{Min}(x) &= \forall y \neg Syx \ , \\ \text{Max}(x) &= \forall y \neg Sxy \end{aligned}$$

and where $\bar{\phi}$ is obtained from ϕ by substituting

- $a(x) \vee \bar{a}(x)$ for $a(x)$,
- $Sxy \vee (\text{Max}(x) \wedge \text{Min}(y))$ for Sxy,
- $x < y < z \vee z < x < y \vee y < z < x$ for $B(x, y, z)$, and
- $Sxy \wedge \Sigma x \wedge \bar{\Sigma} y$ for $G(x, y)$. $\square$

Corollary 4. *Let Q be a chain-invariant $FO\mathcal{L}_{CG}\Sigma$ query. Then $W_{\text{chain}}(Q)$ is a natural projection of an alternating $FO\mathcal{L}_W\Sigma_{\text{alt}}$ query and thus regular.*

Lemma 6. *Let L be the natural projection of an alternating $FO\mathcal{L}_W\Sigma_{\text{alt}}$ query. Then every counter of L is a $(2, \text{odd})$-counter.*

Proof. The core of the proof is to show that L cannot have (n, even)-counters. This is enough because

- any $(2n, m)$-counter gives rise to a $(n, 2m)$-counter (which is an (n, even)-counter), and
- (odd, odd)-counters cannot exist anyway (for any language with words of even length only).

The first claim is easy to see because if (u, v) is a $(2n, m)$-counter, then (u, v^2) is an $(n, 2m)$-counter. The second claim is easy to see as well because if (u, v) were an (n, m)-counter with n and m odd, then there would exist w such that either $uw \in L$ and $uv^n w \in L$ or $uvw \in L$ and $uv^{n+1}w \in L$, but only one of uw and $uv^n w$ has even length, and only one of uvw and $uv^{n+1}w$ has even length.

For the proof that there exist no (n, even)-counters, let L' be the alternating $\text{FO}\mathcal{L}_W\Sigma_{\text{alt}}$ query such that $L = \pi(L')$. Assume (u, v) is an (n, even)-counter of L, say (u, v) is an $(n, 2m)$-counter. Let u' and v' be such that $u'v' \in (\Sigma\bar{\Sigma})(\epsilon + \Sigma)$ and $\pi(u'v') = uv$. We claim that (u', v') is an

$(n, 2m)$-counter of L'. In the proof of this, we will use that if $h(x') = x \in L$ and $x' \in (\Sigma\bar{\Sigma})^*$, then $x' \in L'$.

Since (u, v) is a counter of L, we know there exists w such that $uw \not\leftrightarrow_L uvw$. Let w' be such that $u'v'w' \in (\Sigma\bar{\Sigma})^*$ and $\pi(u'v'w') = uvw$. Then $u'w' \in (\Sigma\bar{\Sigma})^*$ because v' has even length. Therefore, $u'w' \not\leftrightarrow_{L'} u'v'w'$. This verifies the first condition for (u', v') to be a counter.

For the second condition, let $w' \in (\Sigma \cup \bar{\Sigma})^*$ be arbitrary and set $w = \pi(w')$. Assume $u'v'^n w' \in L'$, and thus $uv^n w \in L$ and $uw \in L$, since (u, v) is an $(n, 2m)$-counter of L. We have $u'v'^n w' \in (\Sigma\bar{\Sigma})^*$ and, since v' has even length, $u'w' \in (\Sigma\bar{\Sigma})^*$. Hence, $u'w' \in L'$. For the converse, assume $u'w' \in L'$. We get $uw \in L$. Since (u, v) is an $(n, 2m)$-counter, we also obtain $uv^n w \in L$ and, hence, $u'v'^n w' \in L'$. □

From all this, Proposition 2 follows.

Chainpar-invariant Queries

Recall that we're interested in planar-invariant queries, which are, in particular, chainpar-invariant. The main result of the previous subsection is that chain-invariant FO queries allow only $(2, \text{odd})$-counters. In this section, we show that if an FO query is even chainpar-invariant, the occurrences of $(2, \text{odd})$-counters in the minimal DFA for $W_{\text{chain}}(Q)$ are very restricted.

Let L be a language. We say that (u, v, x, y) is a *two-stage counter* of L if (u, v), (ux, y) and (uvx, y) are counters such that $ux \not\equiv_L uvxy$. When L is a language with $(2, \text{odd})$-counters only, this is equivalent to saying that in A_L, the pattern depicted in Figure 6 does not occur where s_0 and t_1 are required to be distinct.

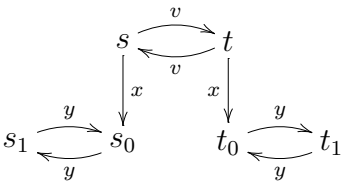

Figure 6: pattern for two-stage counter

We now want to show:

Proposition 3. *For every chainpar-invariant FO$\mathcal{L}_{CG}\Sigma$ query Q, $W_{\text{chain}}(Q)$ has only $(2, \text{odd})$-counters and no two-stage counter.*

For a given alphabet Σ, let Σ_{fold} be the set of all column vectors over Σ with two rows, called folded letters. Words over this alphabet are called folded words. For simplicity, when u and v are words of the same length, say n, then we write $\binom{u}{v}$ for $\binom{u_0}{v_0}\binom{u_1}{v_1}\dots\binom{u_{n-1}}{v_{n-1}}$. When u is a word, we write $\overleftarrow{u}$ for the reverse of u. The unfolding of a word $\binom{u}{v}$, denoted $\lambda(\binom{u}{v})$, is the word $u\overleftarrow{v}$. This definition is extended to sets of words, that is, when L is a language over Σ_{fold}, then $\lambda(L) = \{\lambda(u) \mid u \in L\}$.

Another operation which is useful "rotates" stack words. For every stack word $\binom{u}{v}$ with $u = u'a$ and $v = bv'$, $a, b \in \Sigma$, we write $\binom{u}{v}^{\circlearrowleft}$ for the word $\binom{bu'}{v'a}$. A language L of folded words is said to be rotation-invariant if with u it also contains $u^{\circlearrowleft}$.

Given a $\mathcal{L}_{CG}\Sigma$ query Q, we write $W_{\text{par}}(Q)$ for the set of all words corresponding to parenthetical CB's in Q. The structure of the bijection G in parenthetical CB's induces a natural bijection between folded words and parenthetical CB's. The folded letters correspond to the pairs of the elements of the parenthetical CB that are connected by the bijection G. We write $W_{\text{fold}}(Q)$ for the set of all words over Σ_{fold} corresponding to parenthetical CB's in Q.

Remark 2. *Let Q be a parenthetical-invariant $\mathcal{L}_{CG}\Sigma$ query. Then $W_{\text{par}}(Q)$ is rotation-invariant and*

$$W_{\text{par}}(Q) = \lambda(W_{\text{fold}}(Q)) \ .$$

If Q is even chainpar-invariant, then

$$W_{\text{chain}}(Q) = W_{\text{par}}(Q) = \lambda(W_{\text{fold}}(Q)) \ .$$

As before, for every FO$\mathcal{L}_{CG}\Sigma$ formula ϕ, we want to construct a corresponding $\mathcal{L}_W\Sigma_{\text{fold}}$ formula ϕ_{par}. This is somewhat more complicated.

Lemma 7. *For every FO$\mathcal{L}_{CG}\Sigma$ query Q there exists an FO$\mathcal{L}_W\Sigma_{\text{fold}}$ formula ϕ_{par} such that*

$$W_{\text{fold}}(Q) = W(\phi_{\text{par}}) \ .$$

Proof We only construct ϕ_{par}; the correctness of the construction can easily be proved by induction.

The idea is that a position i in a CB corresponds to two positions j, j' in a folded word where $j' \in \{0, 1\}$. More precisely, when $2m$ is the length of the CB, then i corresponds to $(i, 0)$ when $i < m$ and to $(i, 1)$ when $m \leqslant i < 2m$. We use

$$\begin{aligned} \tau_0(x) &= \text{Min}(x) \ , \\ \tau_1(x) &= \exists y(y < x) \wedge \forall y(y < x \rightarrow \text{Min}(y)) \ , \\ \tau(x) &= \tau_0(x) \vee \tau_1(x) \end{aligned}$$

to identify the positions 0 and 1.

The formula ϕ_{par} is now defined inductively by the following rules.

- $S(x, y)$ is replaced by

$$\begin{aligned} (S(x,y) \wedge x' = y' \wedge \tau_0(x')) \\ \vee (S(y,x) \wedge x' = y' \wedge \tau_1(x')) \\ \vee (\text{Max}(x) \wedge \tau_0(x') \wedge \text{Max}(y) \wedge \tau_1(y')) \\ \vee (\text{Min}(x) \wedge \tau_1(x') \wedge \text{Min}(y) \wedge \tau_0(y'))) \ . \end{aligned}$$

- $B(x, y, z)$ is replaced by

$$\begin{aligned} (x < y < z \wedge \tau_0(x') \wedge \tau_0(y') \wedge \tau_0(z')) \\ \vee (z < y < x \wedge \tau_1(x') \wedge \tau_1(y') \wedge \tau_1(z')) \\ \vee \ldots \end{aligned}$$

- $G(x,y)$ is replaced by

$$x = y \wedge \tau_0(x') \wedge \tau_1(y') \ .$$

- $a(x)$ is replaced by

$$\bigvee_{b\in\Sigma} ((\binom{a}{b}(x) \wedge \tau_0(x')) \vee (\binom{b}{a}(x) \wedge \tau_1(x'))) \ .$$

- $\exists x\phi$ is replaced by $\exists x \exists x'(\tau(x') \wedge \phi_{\text{par}})$,
- $\forall x\phi$ is replaced by $\forall x \forall x'(\tau(x') \to \phi_{\text{par}})$. $\square$

In view of this, Proposition 3 follows from the lemma below.

Lemma 8. *Let L be the unfolding of a rotation-invariant FO$\mathcal{L}_W\Sigma_{\text{fold}}$ query L' and assume L contains only $(2,\text{odd})$-counters. Then L does not contain a two-stage counter.*

Proof. The proof is by way of contradiction. Suppose L contains a two-stage counter where z is such that $uxz \not\leftrightarrow_L uvxyz$. We first "normalize" this counter.

Since v and y have odd length, we can replace v and y by any odd multiple, in particular, we can replace v by $v^{|y|}$ and y by $y^{|v|}$, which means we can assume $|v| = |y|$. Since either $uxz \in L$ or $uvxyz \in L$ and L consists of even-length words only, we conclude that either

- zu and x have even length, or both
- zu and x have odd length.

If the second is true, we simply replace u by uv and x by xy in order to get into the first case. That is, in our "normal form" we have

- $|v| = |y|$ and
- x and zu have even length.

Now let $zu = v_1v_2$ with v_1 and v_2 of the same length and $x = p_1p_2$ with p_1 and p_2 of the same length. We set

$$\alpha = \binom{v_2}{\overleftarrow{v_1}} \ , \qquad \beta = \binom{v}{\overleftarrow{y}} \ , \qquad \gamma = \binom{p_1}{\overleftarrow{p_2}} \ .$$

What we get is that for any even n, $\alpha\beta^n\gamma \not\leftrightarrow_L \alpha\beta^{n+1}\gamma$. But this means L' has a counter—a contradiction. $\square$

This establishes the proof of Proposition 3 as follows. If Q is a chainpar-invariant FO$\mathcal{L}_{CG}\Sigma$ query, then $W_{\text{chain}}(Q)$ is the unfolding of $W_{\text{fold}}(Q)$ and $W_{\text{fold}}(Q)$ is rotation-invariant (Remark 2). Furthermore, $W_{\text{fold}}(Q)$ is an FO$\mathcal{L}_W\Sigma_{\text{fold}}$ query by Lemma 7. Since Q is chainpar-invariant it is, in particular, chain-invariant and hence we can conclude from Proposition 2 that $W_{\text{chain}}(Q)$ does only contain $(2,\text{odd})$-counters. Thus, we can apply Lemma 8 to $W_{\text{chain}}(Q)$ and obtain that $W_{\text{chain}}(Q)$ does not contain a two-stage counter.

Completion of the Invariance Lemma

When Q is a planar-invariant FO$\mathcal{L}_{CG}\Sigma$ query, then the set of words corresponding to the CB's of Q is a language of words of even length. In this subsection we show how to "complete" this language by adding words of odd length such that the resulting language is first-order definable.

Proposition 4. *Let $L = W_{\text{chain}}(Q)$ for a chainpar-invariant FO$\mathcal{L}_{CG}\Sigma$ query Q. Then there is an FO$\mathcal{L}_{W}\Sigma$ query L' such that $L' \cap (\Sigma\Sigma)^* = L$.*

Proof We first describe an automaton for L'. Let $A = A_L$ be the minimal DFA of L, and let S_c be the set of all states from S such that (s, u) is a counter for some u. For every $s \in S_c$, we fix such a u, denote it by u_s, and set $t_s = \delta(s, u_s)$. Then the completion of L is recognized by the automaton

$$A' = (S \cup S \times S, \Sigma, s'_{\text{in}}, \delta, F')$$

where

- $s'_{\text{in}} = s_{\text{in}}$ when $s_{\text{in}} \notin S_c$ and $s'_{\text{in}} = (s_{\text{in}}, t_{s_{\text{in}}})$ when $s_{\text{in}} \in S_c$,
- $\delta'(s, a) = \delta(s, a)$ for all $s \in S$ such that $\delta(s, a) \notin S_c$, $\delta'(s, a) = (\delta(s, a), t_{\delta(s,a)})$ for all other $s \in S$, and $\delta'((s, t), a) = (\delta(s, a), \delta(t, a))$ for all $s, t \in S$,
- $F' = F \cup (S \times F) \cup (F \times S)$.

We first show that $L' \cap (\Sigma\Sigma)^* = L$. By the construction of A' it is obvious that $L \subseteq L'$. Let $w \in L' \cap (\Sigma\Sigma)^*$. If $\delta'(s'_{\text{in}}, w) \in F \cup (F \times S)$, then w is also accepted by A. Assume that $\delta'(s'_{\text{in}}, w) = (s, t) \in S \times F$. Choose $w', w'' \in \Sigma^*$ such that $w = w'w''$ where w' is the shortest prefix of w that is an offset of a counter in A. Let $s_0 = \delta(s_{\text{in}}, w')$, $t_0 = t_{s_0}$, and $u = u_{s_0}$. By the construction of A' we obtain that $w'uw''$ is accepted by A. We know that A only contains $(2, \text{odd})$-counters and hence $|u|$ is odd. Since w is of even length $w'uw''$ must be of odd length, a contradiction to that A only accepts words of even length.

It remains to show that every reachable counter of A' is no counter of L'. First, assume (s, u) is a counter of A' with $s \in S$. Then, by definition of counter and the construction of A', $\delta'(s, u^i) \in S$ for every i, that is, (s, u) must be a counter of A, but then s would not be reachable in A'. Second, assume $((s, t), u)$ is an (n, m)-counter of A'. Then, by definition of counter, $\delta'((s, t), u^n) = (s, t)$ and $|u| = m$. Since L is chainpar-invariant, we immediately have $n = 2$ and m is odd (Proposition 3). By projecting on the two components, we get $\delta'(s, u^2) = s$ and $\delta'(t, u^2) = t$. Let $s' = \delta(s, u)$ and $t' = \delta(t, u)$. By construction of A', we also know there exists a counter (s_0, v) in A with $t_0 = t_{s_0}$ and a word w such that $\delta(s_0, w) = s$ and $\delta(t_0, w) = t$. If $s \neq t'$ or $t \neq s'$, we have a two-stage counter in A—a contradiction to that L is chainpar-invariant (Proposition 3). Otherwise, we have $s = t'$ and $t = s'$. This means $\delta(s, u) = t$ and $\delta(t, u) = s$. Now, for every word x, we have that if $\delta'((s, t), x) = (s'', t'')$, then $\delta'((t, s), x) = (t'', s'')$ (and vice versa), which means that the two states of the counter are equivalent. □

This also proves the Invariance lemma because $W(Q) = W_{\text{chain}}(Q)$ for planar-invariant $\mathcal{L}_{CG}\Sigma$ queries.
